Abstract The effects of electron-hole interaction on the optical properties of a variety of materials have been calculated using an *ab initio* method based on solving the Bethe-Salpeter equation. Results on selected semiconductors, insulators, and semiconducting polymers are presented. In the cases of alpha-quartz (SiO_2) and poly-phenylene-vinylene, resonant excitonic states qualitatively alter the absorption spectra.

1 Introduction

The role of electron-hole interactions in the optical properties of semiconductors and insulators has been long recognized (see *e.g.* [1]). It is possible now to get an accurate description of such properties for a large class of materials from first principles calculations [2–4]. The theoretical framework is based on solving a Bethe-Salpeter equation for the electron-hole amplitude of the 2-particle Green's function[5]. Our approach [2] takes into account electron self energy effects and the interaction between an optically excited electron and the hole left behind. The underlying one-particle (quasiparticle) description is taken within the GW approximation for the electron self-energy [6].

2 Theory

In moderately correlated electron systems, the photo-excited states can be written, to a good approximation, as a linear combination of free electron-hole configurations,

$$|S\rangle = \sum_{cv\mathbf{k}} A^S_{cv\mathbf{k}} |c\mathbf{k}; v\mathbf{k}\rangle \qquad (1)$$

where $|c\mathbf{k}; v\mathbf{k}\rangle$ represents a configuration in which a quasielectron is promoted from the valence band v to the conduction band c. Only vertical transitions are taken into account. From the Bethe-Salpeter equation for the two-particle Green's function, the coefficients $A^S_{cv\mathbf{k}}$ satisfy an eigenvalue equation,

$$(E_{c,\mathbf{k}} - E_{v,\mathbf{k}}) A^S_{cv\mathbf{k}} + \sum_{cv\mathbf{k},c'v'\mathbf{k}'} \mathcal{K}^{c'v'\mathbf{k}'}_{cv\mathbf{k}} A^S_{c'v'\mathbf{k}'} = \Omega^S A^S_{cv\mathbf{k}}$$

$$(2)$$

where $\mathcal{K}^{c'v'\mathbf{k}'}_{cv\mathbf{k}}$ describes the interaction between the excited electron and hole and Ω^S is the energy of state $|S\rangle$. In general, $\mathcal{K}$ is a complicated function that describes the scattering of an electron-hole pair in configuration $|c\mathbf{k}; v\mathbf{k}\rangle$ to $|c'\mathbf{k}'; v'\mathbf{k}'\rangle$. This can be simplified to a screened attractive interaction plus a bare repulsive ex-

change interaction [2]. Dynamical interactions can also be neglected if the energies Ω^S are close to the energy of non-interacting pairs.

The optical absorption is given by

$$\epsilon_2(\omega) = \frac{4\pi^2 e^2}{\omega^2} \frac{1}{V_c} \sum_S |\langle G|\lambda \cdot \mathbf{v}|S\rangle|^2 \delta(\Omega_S - \hbar\omega) \qquad (3)$$

where $|G\rangle$ is the ground state and λ and $\mathbf{v}$ are the polarization vector and the velocity operator, respectively.

The one-particle energies in Eq. (2) are taken from a GWA calculation, as described by Hybertsen and Louie [6].

3 Applications

The measured absorption spectrum of silicon, plotted in Figure 1, shows two well-pronounced peaks at energies about 3.5 eV and 4.2 eV [7]. The calculated results using Eq. (3) reproduce the experimental data very accurately. The minor discrepancies at the energy range 5.5-6.0 eV may be due to the finite sampling of points in the Brillouin zone. The large enhancement in the amplitude of the first peak is due to excitonic effects.

The optical properties of alpha quartz (SiO_2) have been a subject of debate since the 1960's [8]. The presence of a series of four sharp peaks in its absorption spectrum has been recently shown to be due to the formation of resonant excitons [3].

In Figure 2, we show the optical absorption of SiO_2 for polarization perpendicular to the hexagonal plane. The agreement between the experimental spectrum (with peaks at energies 10.3, 11.7, 14.0 and 17.3 eV) and the

calculated spectrum, with excitonic effects included, is again excellent. The fact that an interband transition description gives an almost featureless absorption spectrum shows that the formation of optically active resonant excitonic states dominates the spectrum up to energies about 18 eV.

It is also possible to obtain the binding energy of bound excitons very accurately from Eq. (2), even when this binding energy is only a small fraction of eV. In this case, a careful sampling of the Brillouin zone is required, so that the electronic energy bands are described with the necessary accuracy. Table 1 shows the binding energy of the lowest energy excitonic states in GaAs [2]. In this calculation, we made use of a set of 1000 special k-points near the position of the band extrema.

As an example of a lower-dimensional system, we present results for the conjugated polymer, poly-phenylene-vinylene (PPV), in Figure 3. The difference between the results with and without excitonic effects is striking. The peak at 2.4 eV results from coherent coupled transitions between the highest occupied band and lowest unoccupied band. The resulting exciton has a large binding energy of 0.9 eV. The measured absorption peaks are located at energies 2.5, 3.7, 4.8 and 6.0 eV, which are in quite good agreement with the calculated peak posi-

tions. As in the case of SiO_2, the spectrum of PPV is dominated by resonant excitons.

4 Conclusion

In summary, we have shown that an *ab initio* method, based on solving the Bethe-Salpeter equation, is capable of describing successfully the optical properties of a variety of semiconductors and insulators. The agreement with experimental data is remarkably good. The same analysis can be and have been applied to other systems including surfaces and clusters[2].
